Lab 8: Logistic Regression

Gaston Sanchez

Stat 154, Fall 2017

The Default Data Set

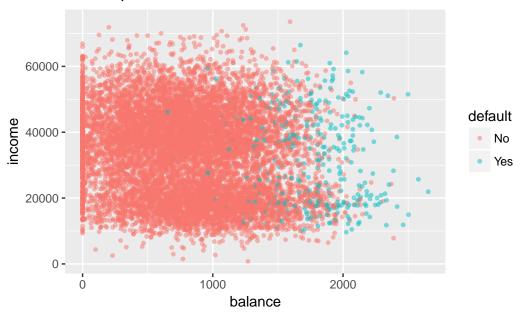

Consider the Default data set that comes in the R package "ISLR". We are interested in predicting whether an individual will default on his or her credit card payment, on the basis of annual income and monthly credit card balance.

```
# remember to load package ISLR!

Begin with some exploratory displays of the data. You can start with a scatterplot of balance and income, distinguishing observations based on default, like in the image below

Scatterplot between Balance and Income

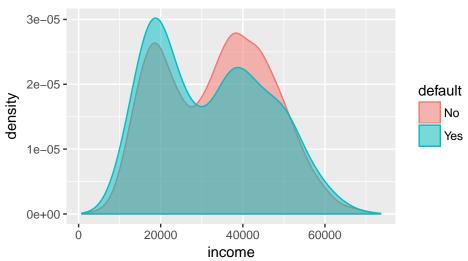

Make density plots of ${\tt balance}$ and ${\tt income},$ for instance:

Kernel Density of Balance (by default)

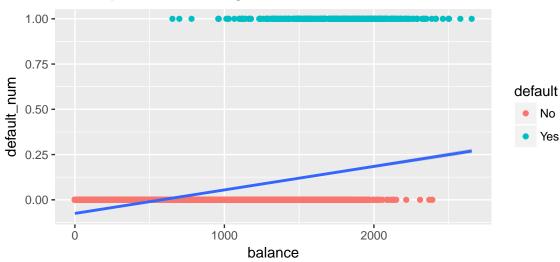

OLS Regression

Out of curiosity, let's fit an OLS model by regressing default on balance. Because default is a factor, you should create a numeric default vector:

```
# code default as numeric
default_numeric <- rep(0, nrow(Default))</pre>
default numeric[Default$default == 'Yes'] <- 1</pre>
Default$default num <- default numeric
ols_reg <- lm(default_num ~ balance, data = Default)</pre>
summary(ols_reg)
##
## Call:
## lm(formula = default_num ~ balance, data = Default)
##
## Residuals:
##
        Min
                  1Q
                       Median
                                     3Q
                                             Max

Logistic Regression

The response default falls into one of two categories: "Yes" or "No". Rather than modeling default directly, logistic regression models the probability that the response Y belongs to a particular category.

The probability of default given balance can be written as:

$$Pr(\text{default} = \text{Yes}|\text{balance})$$

To fit a logistic regression model you use the function glm(). The syntax of glm() is similar to that of lm(), except you must specify the argument family = binomial in order to tell R to run a logistic regression rather than some other type of generalized linear model.

Notice that glm() knows how to handle the response default which is a factor:

```
logreg_default <- glm(default ~ balance, family = binomial, data = Default)
summary(logreg_default)$coefficients</pre>
```

```
## Estimate Std. Error z value Pr(>|z|)
## (Intercept) -10.651330614 0.3611573721 -29.49221 3.623124e-191
## balance 0.005498917 0.0002203702 24.95309 1.976602e-137
```

How do we interpret the coefficients? A one-unit increase in balance is associated with an increase in the log odds of default by 0.005 units.

Many aspects of the logistic regression output shown in the summary() are similar to the lm() output. For example, you can measure the accuracy of the coefficient estimates by computing their standard errors.

To make predictions we can use the coefficient estimates. For instance, the predicted default probability for an individual with a balance of \$1,000 is:

$$\hat{p}(X) = \frac{e^{\hat{\beta}_0 + \hat{\beta}_1 X}}{1 + e^{\hat{\beta}_0 + \hat{\beta}_1 X}} = \frac{e^{-10.6513 + 0.0055 \times 1000}}{1 + e^{-10.6513 + 0.0055 \times 1000}} = 0.00576$$

which is below 1%. In contrast, the predicted probability of default for an individual with a balance of \$2,000 is 0.586 or 58.6%.

Your turn

##

16

• Find out how to use predict() to obtain the probability of default for individuals with balance values of \$100, \$200, \$300, ..., \$2,000

```
# indirect way
b <- predict(logreg default, data.frame(balance = seq(100, 2000, by = 100)))
exp(b) / (1 + exp(b))

17

- Fit a third logistic regression by regressing default on balance, student, and income.
- Are all coefficient estimates significant?
- How would you explain the apparent contradiction between the opposite signs of the student coefficients (this regression versus the previous one)?
- Answer to these questions are in pages 134-137 of ISL.

The Stock Market Smarket Data

You will be working with the Smarket data, which is part of the "ISLR" package. This data consists of percentage returns fro the S&P 500 stock index over 1,250 days, from the beginning of 2001 until the end of 2005. For each date, the percentage returns for each of the five previous tradings has been records, Lag1 through Lag5. Other variables are:

- Volume = the number of shares traded on the prevous day, in billions
- Today = the percentage return on the data in question
- Direction = whether the market was Up or Down on this date

```
# remember to load package ISLR

• Perform a PCA on Smarket[,-9] to get a visual display of the variables. You can accomplish this with the function PCA() from the "FactoMineR" package. By default, it plots a *circle of correlations*

```
pca <- PCA(Smarket[ ,-9], graph = FALSE)</pre>
```

- How correlated are the lag variables with today's returns? Are previous day's returns highly correlated with today's returns?
- Make a scatterplot of Year and Volume

```
with(Smarket, plot(Year, Volume))
lines(lowess(Smarket$Year, Smarket$Volume))
```

Logistic Regression

Use the glm() function to fit a logistic regression model in order to predict Direction using Lag1 through Lag5 and Volume.

```
log_reg <- glm(Direction ~ Lag1 + Lag2 + Lag3 + Lag4 + Lag5 + Volume,</pre>
    family = binomial, data = Smarket)
log_reg
##
          glm(formula = Direction ~ Lag1 + Lag2 + Lag3 + Lag4 + Lag5 +
##
       Volume, family = binomial, data = Smarket)
##
## Coefficients:

## Residual Deviance: 1728 AIC: 1742
```

• Inspect the summary() of the "glm" object containing the output of the logistic regression.

- Looking at the p-values of the regression coefficients, which coefficient seems to be significant?
- What is the coefficient value of Lag1? How would you interpret the sign of this coefficient?
- Use the predict() function to predict the probability that the market will go up, given values of the predictors. Use the argument type = "response" which tells R to output probabilities of the form P(Y = 1|X), as oppose to other information such as the logit. The first 10 probabilities look like this:

Estimation of Parameters

In this part of the lab, your mission is to implement code in R that allows you to estimate the logistic regression coefficients.

The estimation of the coefficients is carried out by Maximum Likelihood. Consider, for instance, a logistic model with one predictor and one response. We look for $\hat{\beta}_0$ and $\hat{\beta}_1$ that maximize the log-likelihood $l(\hat{\beta}_0, \hat{\beta}_1)$. To do so, we set the first order partial derivatives of $l(\beta)$ to zero.

$$\frac{\partial l(\boldsymbol{\beta})}{\partial \beta_0} = \sum_{i=1}^n (y_i - p(x_i)) = 0$$
$$\frac{\partial l(\boldsymbol{\beta})}{\partial \beta_1} = \sum_{i=1}^n x_i (y_i - p(x_i)) = 0$$

Unfortunately, there is no analytical solution to this problem. So how do you actually compute the estimates? Using the Newton-Raphson algorithm.

- Let \mathbf{y} be the column vector of response Y
- Let X be the $n \times (p+1)$ input (design) matrix
- Let **p** be the *n*-vector of fitted probabilities with the *i*-th element $p(x_i; \beta^{old})$
- Let **W** be an $n \times n$ diagonal matrix of weights with *i*-th element $p(x_i; \beta^{old})(1 p(x_i; \beta^{old}))$

Then:

$$\frac{\partial l(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}} = \mathbf{X}^\mathsf{T} (\mathbf{y} - \mathbf{p})$$
$$\frac{\partial^2 l(\boldsymbol{\beta})}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}^\mathsf{T}} = -\mathbf{X}^\mathsf{T} \mathbf{W} \mathbf{X}$$

Newton-Raphson algorithm

Here's the pseudo-code to obtain the estimate coefficients.

- 1. $\mathbf{b}^{\text{old}} \longleftarrow \mathbf{0}$
- 2. Compute **p** by setting its elements to:

$$p(x_i) = \frac{e^{\mathbf{x_i^{\mathsf{T}}b^{old}}}}{1 + e^{\mathbf{x_i^{\mathsf{T}}b^{old}}}}$$

- 3. Compute the diagonal matrix **W** with the *i*-th diagonal element: $p(x_i)(1-p(x_i))$, $i=1,\ldots,n$
- 4. $\mathbf{z} \longleftarrow \mathbf{X}\mathbf{b}^{\mathbf{old}} + \mathbf{W}^{-1}(\mathbf{y} \mathbf{p})$
- 5. $\mathbf{b^{new}} \longleftarrow (\mathbf{X}^\mathsf{T} \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\mathsf{T} \mathbf{W} \mathbf{z}$
- 6. Check whether $\mathbf{b^{old}}$ and $\mathbf{b^{new}}$ are close "enough", otherwise update $\mathbf{b^{old}} \leftarrow \mathbf{b^{new}}$, and go back to step 2.

Your turn: Write code in R for the algorithm described above. Use the Lag variables and Volume as predictors, and Direction as response. You will have to convert Direction into a numeric vector by coverting 'Up' to 1 and 'Down' to 0.

```
# predictors
preds <- c('Lag1', 'Lag2', 'Lag3', 'Lag4', 'Lag5', 'Volume')

# IRLS algorithm
n <- nrow(Smarket)
X <- as.matrix(cbind(Intercept = rep(1, n), Smarket[ ,preds]))
p <- ncol(X)
y <- rep(0, n)
y[Smarket$Direction == 'Up'] <- 1

# start from scratch
b_old <- rep(0, p)
maxiter <- 100
eps <- 1
iter <- 0</pre>
```

```
while ((eps > 0.0001) \mid (iter == maxiter)) {
  # probabilities
  Xb <- as.vector(X %*% b_old)</pre>
  exb <- exp(Xb)
  probs \leftarrow exb / (1 + exb)
  # matrix W
  W <- diag(probs * (1 - probs), nrow = n, ncol = n)
  z <- X %*% b_old + solve(W) %*% (y - probs)</pre>
  b new <- solve(t(X) %*% W %*% X) %*% t(X) %*% W %*% z
  b_diff <- abs(b_new - b_old)</pre>
  eps <- sum(b diff)
  iter <- iter + 1
  b old <- b new
}
# compare with qlm() output
cbind(b new, log reg$coefficients)
```

```

Simplified Algorithm

Since **W** is an $n \times n$ diagonal matrix, direct matrix operations with it may be very inefficient. A modified pseudo code is provided next.

- 1. $\mathbf{b}^{\mathbf{old}} \longleftarrow \mathbf{0}$
- 2. Compute **p** by setting its elements to:

$$p(x_i) = \frac{e^{\mathbf{x_i^T} \mathbf{b^{old}}}}{1 + e^{\mathbf{x_i^T} \mathbf{b^{old}}}}$$

3. Compute the $n \times (p+1)$ matrix $\tilde{\mathbf{X}}$ by multiplying the *i*-th row of matrix \mathbf{X} by $p(x_i)(1-p(x_i)), \quad i=1,\ldots,n$

```
4. \mathbf{b^{new}} \longleftarrow \mathbf{b^{old}} + (\mathbf{X}^\mathsf{T}\tilde{\mathbf{X}})^{-1}\mathbf{X}^\mathsf{T}(\mathbf{y} - \mathbf{p})
```

5. Check whether $\mathbf{b^{old}}$ and $\mathbf{b^{new}}$ are close "enough", otherwise update $\mathbf{b^{old}} \leftarrow \mathbf{b^{new}}$, and go back to step 2.

Your turn: Write code in R for the simplified algorithm described above. Use the Lag variables and Volume as predictors, and Direction as response. You will have to convert Direction into a numeric vector by coverting 'Up' to 1 and 'Down' to 0.

```
# IRLS algorithm
n <- nrow(Smarket)</pre>
X <- as.matrix(cbind(Intercept = rep(1, n), Smarket[ ,preds]))</pre>
p \leftarrow ncol(X)
y \leftarrow rep(0, n)
y[Smarket$Direction == 'Up'] <- 1
# start from scratch
b_old \leftarrow rep(0, p)
maxiter <- 100
eps <- 1
iter <- 0
while ((eps > 0.0001) \mid (iter == maxiter)) {
  # probabilities
  Xb <- as.vector(X %*% b old)</pre>
  exb <- exp(Xb)
  probs \leftarrow exb / (1 + exb)
  # matrix W
  W <- probs * (1 - probs)
  X \text{ tilde } \leftarrow \text{sweep}(X, 1, W, FUN = "*")
  b_new <- b_old + solve(t(X) %*% X_tilde) %*% t(X) %*% (y - probs)</pre>
  b diff <- abs(b new - b old)</pre>
  eps <- sum(b_diff)</pre>
  iter <- iter + 1
  b old <- b new
}
# compare with qlm() output
cbind(b_new, log_reg$coefficients)
##
